Abstract

Network growth can be framed as a competition for edges among nodes in the network. As with various other social and physical systems, skill (fitness) and luck (random chance) act as fundamental forces driving competition dynamics. In the context of networks, cumulative advantage (CA) – the rich-get-richer effect – is seen as a driving principle governing the edge accumulation process. However, competitions coupled with CA exhibit non-trivial behavior and little is formally known about duration and intensity of CA competitions. By isolating two nodes in an ideal CA competition, we provide a mathematical understanding of how CA exacerbates the role of luck in detriment of skill. We show, for instance, that when nodes start with few edges, an early stroke of luck can place the less skilled in the lead for an extremely long period of time, a phenomenon we call “struggle of the fittest”. We prove that duration of a simple skill and luck competition model exhibit power-law tails when CA is present, regardless of skill difference, which is in sharp contrast to the exponential tails when fitness is distinct but CA is absent. We also prove that competition intensity is always upper bounded by an exponential tail, irrespective of CA and skills. Thus, CA competitions can be extremely long (infinite mean, depending on fitness ratio) but almost never very intense. The theoretical results are corroborated by extensive numerical simulations. Our findings have important implications to competitions not only among nodes in networks but also in contexts that leverage socio-physical models embodying CA competitions.

I. INTRODUCTION

Growth is a fundamental aspect inherent to most networks that has been widely investigated both empirically through the analysis of data from various contexts and theoretically through idealized models. An important driving force behind network growth and in particular the evolution of node degrees is cumulative advantage (CA), where accumulated edges (i.e., current node degree) promote gathering even more edges. A second widely-accepted driving force in this context is fitness, which captures the inherent ability of nodes to attract edges. Thus, dynamics of network growth is governed by skill (fitness) and luck (random but biased edge attachment).

Recent work has framed the problem of network growth as a competition among nodes [1-3]. In essence, nodes in a network compete with one another to accumulate edges, increasing (or decreasing) their degrees over time. As expected, such competitions are also driven by skill and luck and have been studied empirically and theoretically for different networks, an example of which is the evolution and predictability of success in citation networks [2]. Outside the domain of networks, the study of skill and luck competitions have a long history in social and physical sciences [1, 4-5].

However, the intricacies of skill and luck competitions are far from trivial, even in a simple CA model with just two competitors. To illustrate, consider a network with two hub nodes that compete for connectivity. Each time a new node joins the network, it connects to one of the hubs randomly with bias depending on the hubs’ fitnesses (model details given in Section III). In the presence of CA, the bias also depends on the hubs’ current degrees. Figure 1a and Figure 1b illustrate the difference of the hubs’ degrees over time for two sample paths in the absence and presence of CA, respectively. The paths with the same color and label in both plots are generated using the same pseudorandom sequence. The competition is tied every time the degree difference is zero and we define the competition duration as the time until the final tie occurs. Note that when generated by the same pseudorandom sequence, a competition with CA can last either much shorter (see the red paths in Figure 1a) or significantly longer (see the blue paths in Figure 1a) than without CA, pointing to a large variance in competition duration. Moreover, with CA the less fit hub enjoys a sizable degree leadership for a long time. These observations also apply to two specific nodes in more general network growth models, provided that we interpret time as the total degrees of the
two nodes of interest. However, are these sample paths anomalies or the norm? Can we be more precise about these observations?

![Graphs showing time evolution of degree difference between two nodes in competitions without and with cumulative advantage (CA).](image)

(a) Competition without CA.  
(b) Competition with CA.

FIG. 1. Time evolution of degree difference between two nodes in competitions without and with cumulative advantage (CA). Each plot shows two independently simulated sample paths. The sample paths with the same color in both plots use the same sequence of pseudorandom numbers. Competition starts tied and node \( X \) is 10% fitter than node \( Y \). See model details in Section III.

In this work, we aim to develop a fundamental understanding of the effects of CA in competitions. We approach this problem by considering classical, simple and well-studied theoretical models for competitions based on skill and luck that are either coupled with or free of cumulative advantage. These models may not be general enough as statistical models that fit real-world data for competitions in growing networks, as such models must capture intricate features of the domain, such as skill distribution or amplitude of cumulative advantage (e.g., linear or sub-linear), as well as their time dependency. However, they still provide invaluable insights into how CA impacts competitions. More specifically, we focus on competitions between two agents (nodes) and study two fundamental aspects of competitions: \textit{duration} – the time required for the most skilled to overtake its competitor and forever enjoy undisputed leadership; \textit{intensity} – the number of times competitors tie for the leadership. In this direction, we make the following main contributions.

- In the case where the two competitors have equal fitness, we obtain the asymptotic tail distributions for both duration and intensity of CA competitions. We demonstrate that they are power laws with respective tail exponents \(-1/2\) and \(-1\), which are independent of the initial wealth of the competitors.
• In the case where the two competitors have unequal fitness, we derive asymptotic lower and upper bounds for the tail distribution of duration of CA competitions, and an upper bound for the tail distribution of their intensity. These bounds show that duration is heavy tailed while intensity is exponential tailed in the presence of CA. In particular, duration is heavier tailed while intensity is lighter tailed than corresponding RW competitions.

• We observe that a slight difference in fitness of the two results in a extremely heavy tail for duration of CA competitions. Thus, an individual that is only slightly more skilled than his competitor might have to hang on to the competition for an extremely long period of time before taking the ultimate lead, a phenomenon we call the “struggle of the fittest”.

Despite 90 years since the basic CA model was first proposed [6], known as Pólya’s urn model, our work is, to the best of our knowledge, the first to characterize the duration and intensity distributions of CA competitions with skill. We believe our findings have profound implications to our understanding of competitions, beyond its importance to the evolution of degree of nodes in growing networks.

The rest of the paper is organized as follows. Section II briefly discusses the related work. Section III introduces the CA competition model. Section IV presents the theoretical results, illustrated and supplemented by simulations. Section V concludes the paper.

II. RELATED WORK

Resource accumulation is an ubiquitous phenomenon that naturally arises in a variety of social and complex systems. The problem is usually framed as a competition among agents for resources that are abundant, and has been studied in different contexts across various disciplines ranging from protein binding within a cell [7, 8] to views of online social media [9, 10] and citations among scholarly papers [2, 11]. In the context of networks, network growth and in particular node degree evolution has been recently framed as competition among nodes, where different aspects of competitions have been studied empirically and theoretically [1, 3, 12, 13].

Models for resource accumulation competitions generally incorporate skill (fitness), luck
(randomness) and externalities. Cumulative advantage is one type of externality that is considered a general mechanism for inequality [5]. It appears in the literature under many variants such as Price’s cumulative advantage model [11], preferential attachment [14-16], “the rich get richer”, Matthew effect [5, 17, 18], and path-dependent increasing returns [11]. The Pólya’s urn model [6, 19] is widely used to capture these effects. Most previous work on Pólya’s urn model and its generalizations focuses on the share of resources gathered by each agent, also known as the agent’s market share, proving convergence and limiting results of the market share distribution [19-21]. More recent studies consider Pólya’s urn models with non-linear bias [22], the effects of initial conditions of urns [23, 44], as well as the time for the first tie [25] and probability of a tie ever occurring [26].

However, two fundamental metrics associated with competitions, duration - how long it takes for the undisputed winner to emerge, and intensity - how many times the competitors tie for the leadership, have largely been neglected in the literature. Previous results establish that the most skilled agent eventually wins [19], and that average intensity up to time \( t \) is approximately \((\log t)^{\alpha}\), where \( \alpha \) depends on the relative skill of the competitors [12, 27]. To the best of our knowledge, no previous work has provided rigorous characterizations for the distributions of duration and intensity of competitions in Pólya’s urn models. Our work partially fills this gap for the two competitor case and sheds light on some recent approximate results [12, 27].

III. MODELS

In this section, we formally introduce competition models for two competing agents and give precise definitions for two fundamental metrics of a competition, i.e. its duration and intensity.

A. General Setup and Metrics

Let \( X \) and \( Y \) denote the two agents that engage in the competition. Each agent is associated with a positive fitness value that reflects its intrinsic competitiveness or skill level. Let \( f_X \) and \( f_Y \) denote the fitness of \( X \) and \( Y \), respectively, and \( r = f_X/f_Y \) the fitness ratio. Without loss of generality, we assume that \( f_X \geq f_Y \) and hence \( r \geq 1 \).
The resource that the agents compete for will be generically referred to as wealth, which is measured in discrete units. The competition starts at time $t = 0$ with agents $X$ and $Y$ having $x_0$ and $y_0$ units of initial wealth, respectively. We consider a discrete-time process. At each time step, one unit of wealth is added to the system and given to either $X$ or $Y$. Denote by $X_t$ and $Y_t$ the respective cumulative wealth of $X$ and $Y$ at time $t$. The complete history of the competition $\{(X_t, Y_t)\}_{t=0}^\infty$ then forms a discrete-time discrete-space stochastic process. The state space $S$ is the first quadrant of the integral lattice (see Figure 2),

$$S = \{(x, y) \in \mathbb{Z}^2 : x \geq 1, y \geq 1\}.$$ 

The initial condition is $(X_0, Y_0) = (x_0, y_0)$. How the process evolves over time is defined by specific competition models, of which the CA competition model to be introduced in Section III B is an example.

We now make the notions of duration and intensity of competitions more precise by defining them through events of wealth ties. Given a competition process $\{(X_t, Y_t)\}_{t=0}^\infty$, we say that a tie occurs at time $t$ if $X_t = Y_t$. Figure 2 shows three ties at times $t = 3, 5, 7$.

The duration $T$ of a competition is defined to be the time of the last tie, i.e.,

$$T = \sup\{t \geq 0 : X_t = Y_t\}.$$

When there is no tie, we follow the standard convention that $T = \sup\emptyset = -\infty$. The competition ends at time $T$ in the sense that one of the agents takes the lead and never lose it again after $T$. 

FIG. 2. State space of competition processes, with an illustration of a sample path with $x_0 = 2$, $y_0 = 1$, and three ties at time $t = 3, 5, 7$. 
The intensity $N_t$ of a competition until time $t$ is the number of ties that occur by time $t$, i.e.,

$$N_t = \sum_{i=0}^{t} 1\{X_i = Y_i\},$$

where $1\{A\}$ is the indicator of event $A$. The intensity $N$ of a competition is the total number of ties throughout the competition, i.e., $N = \lim_{t \to \infty} N_t$. This measures the intensity of the competition in the sense that it counts the number of potential changes in leadership. Note that $T < +\infty$ if and only if $N < +\infty$.

### B. CA Competition Model

In the CA competition model, the unit of wealth introduced at time $t+1$ is given to $X$ with probability

$$p_{X,t} = \frac{f_X X_t}{f_X X_t + f_Y Y_t} = \frac{rX_t}{rX_t + Y_t};$$

otherwise it is given to $Y$. Note that the transition probability $p_{X,t}$ embodies both fitness and CA effects (externalities).

More formally, in the CA competition model, the complete history $\{(X_t, Y_t)\}_{t=0}^{\infty}$ forms a discrete-time Markov chain with stationary transition probabilities. The transition probability $\mathbb{P}[(X_{t+1}, Y_{t+1}) = (x', y') \mid (X_t, Y_t) = (x, y)]$ is given by

$$Q_{CA,r}(x, y; x', y') = \begin{cases} \frac{rx}{rx + y}, & \text{if } (x', y') = (x + 1, y), \\ \frac{y}{rx + y}, & \text{if } (x', y') = (x, y + 1), \\ 0, & \text{otherwise.} \end{cases} (1)$$

Note that the transition probabilities are spatially inhomogeneous, i.e., they depend on the current state $(x, y)$, which makes the analysis difficult, especially when $r > 1$. For the purpose of comparison, a RW competition model incorporates skill and luck but not the CA effect (no externalities), where the transition probabilities are determined entirely by the fitness ratio $r$. In particular, the probability that agent $X$ receives the unit of wealth introduced at any time is always given by

$$p_X = \frac{f_X}{f_X + f_Y} = \frac{r}{r + 1}.$$
Thus the RW competition model is a discrete-time Markov chain with the same state space $S$ as the CA competition model, but with the following spatially homogeneous transition probabilities,

$$Q_{RW,r}(x, y; x', y') = \begin{cases} 
\frac{r}{r+1}, & \text{if } (x', y') = (x + 1, y), \\
\frac{1}{r+1}, & \text{if } (x', y') = (x, y + 1), \\
0, & \text{otherwise.}
\end{cases}$$

The spatial homogeneity of the transition probabilities leads to a more tractable analysis. In fact, the difference process $\{X_t - Y_t\}$ is a standard biased RW with parameter $r/(r + 1)$. Thus the abundance of known results for RW [28] can be directly translated into results for RW competitions, including duration and intensity as we have defined in Section III A.

Throughout the rest of the paper, we use CA and RW to denote CA and RW competitions with identical fitness ($r = 1$), respectively. We use CA and RW to denote CA and RW competitions with distinct fitnesses ($r > 1$), respectively. Before presenting our results, we point out here some connections between the CA and RW models that are useful in our analysis. In particular, in CA, all paths connecting two given states $(x_0, y_0)$ and $(x, y)$ have the same probability. This is a nice property that CA shares with RW, which enables us to leverage existing results on RW in our analysis of CA. Unfortunately, this property is lost in CA, where we resort to the Chapman-Kolmogorov equation for upper and lower bounds on the probabilities of interest. In the limiting case where $X_t$ and $Y_t$ are both large but comparable to each other, the connection to RW is again partially retained, a fact we also exploit in the analysis of CA.

IV. RESULTS

In this section we present our theoretical results for duration and intensity distributions, which are also illustrated graphically and supported by extensive numerical simulations. Table I provides a summary of our main results along with prior knowledge about RW competitions from the literature. Note that $P_{(MODEL),r}^{(x_0,y_0)}$ denotes the probability in model $(MODEL) \in \{CA, RW\}$ with fitness ratio $r$ and initial state $(x_0, y_0)$. The following notations have been used in Table I and will be used throughout the rest of the paper.

- $f(x) \sim g(x)$ if and only if $\lim_{x \to \infty} f(x)/g(x) = 1$.

TABLE I. Tail distributions for duration and intensity of competitions in both RW and CA models. Multiplicative constants are omitted in all expressions involving $t$ and $n$. The RW statistics can be found in most textbooks on the topic, e.g. [28, pp. 113,116].

- $f(x) \lesssim g(x)$ if and only if $\limsup_{x \to \infty} f(x)/g(x) \leq 1$.

- $f(x) \gtrsim g(x)$ if and only if $\liminf_{x \to \infty} f(x)/g(x) \geq 1$.

All proofs are relegated to Appendix A.

### A. Competition Duration

As shown in Table I, RW$_\neq$ competitions never end, i.e., $\mathbb{P}_{\text{RW},1}^{(x_0,y_0)}[T = \infty] = 1$, while RW$_\neq$ competitions are generally very short, whose durations exhibit exponential tails. The story for CA competitions is drastically different. The introduction of CA guarantees that a competition always ends, i.e. $\mathbb{P}_{\text{CA},r}^{(x_0,y_0)}[T < \infty] = 1$, even when the two agents are equally fit, which is in sharp contrast to endless RW$_\neq$ competitions. On the other hand, CA fundamentally increases the chance of having a long-lasting competition between unequally fit agents, as the duration of CA$_\neq$ always has a power-law distribution, in contrast to a sub-exponential distribution for RW$_\neq$. Thus, cumulative advantage does not always make competitions shorter as one might expect.
1. Equal Fitness Case: \( \text{CA}_\mp \)

The following theorem shows that the duration \( T \) for \( \text{CA}_\mp \) is heavy-tailed with an asymptotic power-law distribution.

**Theorem 1.** The duration of a \( \text{CA}_\mp \) competition has the following asymptotic tail distribution,

\[
P^{(x_0,y_0)}_{\text{CA,1}} \left[ T \geq t \right] \sim \frac{1}{2^{x_0+y_0-5/2} \pi B(x_0,y_0)} t^{-1/2},
\]

where \( B(x,y) = \int_0^1 s^{x-1}(1-s)^{y-1} \, ds \) is the beta function.

It follows from (2) that

\[
P^{(x_0,y_0)}_{\text{CA,1}} \left[ T < \infty \right] = 1 - \lim_{t \to \infty} P^{(x_0,y_0)}_{\text{CA,1}} \left[ T \geq t \right] = 1,
\]
i.e. the duration of \( \text{CA}_\mp \) is almost surely finite.

Note, however, that the power-law exponent is always \(-1/2\), independent of the initial wealth \( x_0 \) and \( y_0 \). Consequently, although the duration of \( \text{CA}_\mp \) is finite rather than infinite as in \( \text{RW}_\mp \), the expected duration is still infinite, even if \( x_0 \) is significantly larger than \( y_0 \) or vice versa.

On the other hand, the initial wealth \((x_0,y_0)\) does affect the location of the distribution. Figure 3 shows the duration distributions from simulations for various values of initial wealth, with the asymptotes in Eq. (2) superimposed. Each simulation curve is the average of \(10^5\) independent runs for \(10^7\) time steps each. All curves are truncated at \( t = 10^6 \), since the empirical distributions will drop down sharply and become inaccurate as \( t \) approaches the cutoff time in simulations. Similar truncations will be applied to later plots without further mention. Note the good agreement between theory and simulation in the tails in Figure 3. When both \( x_0 \) and \( y_0 \) increase but are kept equal, the distribution curve shifts upwards, which means the competition lasts longer. When the initial wealth of only one agent (\( y_0 \) here) increases, the distribution curve shifts downwards, which means the competition is shorter.

2. Different Fitness Case: \( \text{CA}_{\neq} \)

The next theorem shows that the tail distribution of the duration \( T \) for \( \text{CA}_{\neq} \) is asymptotically bounded by power laws from both below and above.
Theorem 2. The tail distribution of the duration of a CA\(\neq\) competition has the following asymptotic bounds,

\[
\varphi_1 t^{-(r-1)x_0} \lesssim \mathbb{P}_{CA,r}^{(x_0,y_0)}[T \geq t] \lesssim \varphi_2 t^{-(r-1)(x_0-1/r)} ,
\]

where

\[
\varphi_1 = \frac{\Gamma(r x_0 + y_0)}{(r + 1)x_0 2^{x_0+y_0-1} \Gamma(x_0) \Gamma(y_0)} ,
\]

and

\[
\varphi_2 = \frac{2^{(r-1)(x_0-r-1)} \Gamma(r-1) \Gamma(r x_0 + y_0)}{(r+1)(x_0-r-1) \Gamma(x_0) \Gamma(y_0)} ,
\]

where \(\Gamma(x) = \int_0^\infty s^{x-1} e^{-s} ds\) is the gamma function.

It follows from the lower bound that \(\mathbb{P}_{CA,r}^{(x_0,y_0)}[T < \infty] = 1\) for \(r > 1\), i.e. the duration for CA\(\neq\) is almost surely finite as is for CA\(_-\). The constants \(\varphi_1\) and \(\varphi_2\) are very loose, so the bounds are best interpreted as bounds on the tail exponent.

Note that the power-law exponents in the upper and lower bounds depend on \(x_0\) but not on \(y_0\), and they differ only by \(1 - 1/r < 1\). In this sense, the shape of the distribution at large \(t\) is largely determined by the fitness ratio and the initial wealth of the fitter agent, while the initial wealth of the less fit plays a much weaker role. This is illustrated in Figure 4, which shows the duration distributions from simulations for \(r = 1.2\) and various values of \((x_0, y_0)\), alongside the lower bounds from Eq. (3) that are shifted closer to the simulation results for easier comparison of the slopes. Each simulation curve is the average of \(10^5\) independent runs for \(10^9\) time steps each.
Figure 4 shows how the slopes of the distribution curves, which correspond to the power-law exponents, depend critically on $x_0$. The impact of $x_0$ is two-fold. As $x_0$ increases, the distribution curve becomes more tilted as predicted by the bounds. At the same time, it also shifts downwards. Both changes mean that the competition tends to be shorter.

Figure 4b shows the impact of changing both $x_0$ and $y_0$. When $x_0$ is fixed, increasing $y_0$ only results in a slight decrease in the absolute value of the slope, in agreement with Eq. (3). The distribution curve shifts upwards, which means the competition tends to last longer. When both $x_0$ and $y_0$ increase, the situation becomes more intricate. The curve may shift upwards while bending down faster in the tail, which could possibly lead to a crossover in the old and new curves, as is the case of going from $(x_0, y_0) = (1, 1)$ to $(x_0, y_0) = (3, 3)$. In this case, the new competition is more likely to have a medium long duration.

3. **Struggle-of-the-Fittest Phenomenon**

Now we look at the impact of fitness ratio $r$ on duration. Contrasting Eqs. (2) and (3) leads to an interesting observation. Departing from CA with fitness ratio $r$ from 1 to $1 + \varepsilon$, where $\varepsilon$ is close to 0, precipitates a significant increase in the probability of long-lasting competitions, as manifested in the discontinuous jump in the
power-law exponents from $-1/2$ in Eq. (2) to $-\varepsilon x_0 \approx 0$ in Eq. (3). This is opposite to what happens in RW competitions, where a slight increase in fitness departing from RW to RW$\neq$ transforms the competition from one that never ends to one with a geometrically distributed duration. The lower bound in Eq. (3) shows that CA$\neq$ with $r < 1 + (2x_0)^{-1}$ is more likely to have long-lasting competitions than CA$=$, despite the fact that the fitter agent is bound to become the ultimate winner. We refer to the phenomenon that the fitter agent takes an extremely long time to win as “struggle of the fittest”.

Figure 5 shows the duration of simulated CA competitions for various fitness ratios $r$. Each simulation curve is the average of $10^5$ independent runs for $10^9$ time steps each. Note how the distribution of duration jumps upward from the curve for CA$=$ to the curve for CA$\neq$ with $r = 1.1$. It also shows how the curves for CA$\neq$ become more and more tilted as $r$ increases, being roughly parallel to the CA$=$ curve at $r = 1 + (2x_0)^{-1} = 1.5$.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure5.png}
\caption{Tail distribution for duration of CA with various $r$. The dots are simulation results. For $r = 1$, the solid line is the asymptote in Eq. (2). For $r > 1$, the solid lines are the lower bound in Eq. (3) but shifted as in Figure 4.}
\end{figure}

B. Competition Intensity

Given that CA competitions are long-lasting, one might expect them also to be intense, i.e., exhibit many ties ($X_t = Y_t$). As we will see in this section, this intuition is appropriate for CA$=$ but not for CA$\neq$.
1. Equal Fitness Case: $CA_=$

The following theorem shows that the intensity $N$ of $CA_=$ is heavy-tailed with an asymptotic power-law distribution.

**Theorem 3.** The intensity of a $CA_=$ competition has the following asymptotic tail distribution,

$$
P_{CA,1}^{(x_0, y_0)} [N \geq n] \sim \frac{1}{2^{x_0+y_0-2} B(x_0, y_0)} n^{-\alpha},$$

where $B(x_0, y_0)$ is the beta function as in Eq. (2).

In this case, the intensity has infinite expectation, as does the duration. Figure 6 shows the duration distributions from simulations for various values of initial wealth, with the asymptotes in Eq. (6) superimposed. Each simulation curve is the average of $10^5$ independent runs for $10^7$ time steps each. We observe the same behavior as in Figure 3. When both $x_0$ and $y_0$ increase but are kept equal, the distribution curve shifts upwards, which means the competition is more intense. When the initial wealth of only one agent ($y_0$ here) increases, the distribution curve shifts downwards, which means the competition is less intense.

We mention in passing that if we have a finite observation time $t_f$, the expected intensity $N_{t_f}$ by time $t_f$ grows as $\log t_f$, a phenomenon observed for the related CA model in Godrèche et al. [12].

2. Different Fitness Case: $CA_≠$

In sharp contrast, $CA_≠$ competitions are not intense despite their long durations. In fact their intensities are surprisingly mild, bounded above by a geometric distribution, as shown in the next theorem.

**Theorem 4.** The tail distribution of the intensity of a $CA_≠$ competition has the following upper bound,

$$
P_{CA,r}^{(x_0, y_0)} [N \geq n] \leq C \left( \frac{2}{1 + r} \right)^{n-1},$$

with

$$C = \begin{cases} 
1, & x_0 \leq y_0, \\
\frac{(y_0-x_0)^{x_0-y_0} (1 + \frac{1}{r})^{x_0-y_0}}{(x_0+y_0)^{x_0+y_0}} (1 + \frac{1}{r})^{x_0-y_0}, & x_0 > y_0,
\end{cases}$$

where $(x)_k = \prod_{i=0}^{k-1} (x + i)$ is the Pochhammer symbol.
FIG. 6. Tail distribution for intensity of CA with various \((x_0, y_0)\). The dots are simulation results. The solid lines are the asymptotes from Eq. (6).

FIG. 7. Tail distribution for intensity of CA with various \(r\). The dots are simulation results. The solid lines are the upper bounds from Eq. (7) for \(r > 1\), and the asymptote in Eq. (6) for \(r = 1\).

Note that the expectation and all higher moments of \(N\) are finite. Therefore, the intensity of a CA competition changes dramatically when the fitnesses of the two parties become unequal, the distribution shifting from a power-law tail to an exponential tail. This is illustrated in Figure 6, where each simulation curve is the average of 10^5 independent runs for 10^9 time steps each. An important observation is that both CA and RW competitions have intensities that are upper bounded by identical exponential tails (see Table I), while exhibiting fundamentally different durations.

Why are CA competitions simultaneously not intense and long-lasting? The answer resides in the probability of \(Y\) being the eventual winner. In CA competitions, \(Y\) wins with probability \(y_0/(x_0+y_0)\), while in CA competitions \(Y\) (the less fit) never wins. However, for small values of \(r\), especially for those very close to one, the dynamics in the initial stages of the competition closely follows that of CA. Thus there is a non-negligible chance that \(Y\) takes a significant lead, with the CA effect helping it uphold the lead for a long period of time over which there is no tie. Eventually, however, fitness effect outweighs the CA effect, and \(X\) catches up with \(Y\). By then they both have large accumulated wealth, which makes CA behave like RW in the vicinity of \(X = Y\), allowing \(X\) to quickly establish a lead ahead of \(Y\). At this final stage both fitness and CA effects work in favor of \(X\), and \(Y\)
stands little chance in taking the lead again. To summarize, the less fit agent has a non-negligible probability of taking an early lead which can last for a very long time due to the CA effect, but it will ultimately surrender the lead to the fitter agent and never lead again, a phenomenon that we call “delusion of the weakest”, which is the flip-side of “struggle of the fittest”.

Figure 8 illustrates this observation by showing sample paths for different values of \( r \), all generated using the same sequence of random bits. Note that for \( r = 1 \) (identical fitness), \( Y \) wins quickly, whereas for \( r = 1.1 \) the fitter agent \( X \), having trailed behind for a long time, eventually takes over after 69,426 time steps. Finally, for both \( r = 1.2 \) and \( r = 1.5 \) agent \( X \) has no trouble quickly winning the competition. These sample paths showcase the long struggle of the “slightly” fitter agent in competitions with CA effects.

FIG. 8. “Delusion of the weakest”: sample paths for different values of \( r \) \((x_0 = y_0 = 1)\), all generated using the same sequence of random bits

C. Interplay of Duration and Intensity

In this section, we study the relationship between duration and intensity. Note that duration gives a natural upper bound \( N \leq T/2 \) for intensity, i.e., the number of ties is at most half of the duration in any competition. In CA\(_-\), duration and intensity are strongly and positively correlated. In fact, a tie at time \( t \) increases the probability of having another tie at a time greater than \( t \). More precisely, [25] shows that for CA\(_-\),

\[
\mathbb{P}_{CA,1}^{(x_0,y_0)} [T > t | X_t = Y_t] \approx 1 - \frac{1}{\sqrt{\pi X_t}}.
\]
FIG. 9. Scatter plot of duration vs. intensity for CA=.

FIG. 10. Conditional average intensity of competitions conditioned on their duration being at least $t$, namely $\mathbb{E}_{CA,r}[N \mid T \geq t]$.

Since $X_t \sim t/2$ at a tie, Eq. (8) implies that the later a tie occurs, the more likely another tie will occur, intuitively explaining why long-lasting competitions are also intense in this case.

Figure 9 shows a scatter-plot of duration versus intensity from $10^4$ independent runs of CA= competitions with $x_0 = y_0 = 1$, each simulated for $10^9$ time steps. This unveils a strong positive linear correlation between the two statistics in log-log scale (sample Pearson correlation coefficient of 0.94).

Interestingly, CA$\neq$ shows a different behavior, since even long-lasting competitions exhibit only a small number of ties. Figure 10 shows simulation results for conditional average intensities of competitions with $x_0 = y_0 = 1$ and different fitness ratios $r$, conditioned on the duration being at least $t$. Each simulation curve is obtained from $10^4$ independent runs for $10^9$ time steps each. Note that for $r = 1$, the conditional average intensity increases linearly with $t$, but for $r > 1$, it stabilizes as $t$ increases. Again, we observe a sharp transition as we move from identical to distinct fitnesses, this time in the correlation between intensity and duration.

V. DISCUSSION AND CONCLUSION

As supported by various empirical studies over the last century, real world competitions for resource accumulation seem to be subject to cumulative advantage effects, at least to
some extent. Because of such findings and the fact that CA generally leads to large inequalities in resource distribution, understanding the role of skill and luck in competition dynamics becomes a pressing issue both in theory and practice. Indeed, recent empirical \[2, 29, 30\] and theoretical \[11, 12, 22, 31\] studies have contributed in this direction.

However, contrary to prior theoretical works, we consider simple and classical mathematical models that capture just the essence of skill and luck competitions with and without CA effects, and investigate fundamental aspects of competition, namely duration (i.e., time until ultimate winner emerges) and intensity (i.e., number of ties in competition). By considering simple models and simple properties we prove and illustrate fundamental theoretical results: CA effect exacerbates the role of luck - power-law tail duration emerges regardless of skill differences, and become extreme (i.e., infinite mean) when skill differences are small enough. Moreover, duration is long not necessarily because of intense competition where agents tussle aggressively for ultimate leadership. On the contrary, under CA, competitions are generally very mild, exhibiting an exponential tail. Long competitions emerge when an early stroke of luck places the less skilled in the lead, who can then, boosted by CA effects, enjoy leadership for a very long period of time. Thus, when CA is present luck sides with the less skilled.

The non-negligible probability of long-lasting competitions has far-reaching implications. In the absence of CA, it takes very little time for the fittest agent to establish dominance, so it is often reasonable to neglect the possibility of a premature burnout. Such observations are in hand with the “survival of the fittest” principle, since soon enough the more skilled will prevail. In the presence of CA, however, even agents with superior fitness may face the challenge of having to endure extremely long competitions. This challenge becomes all more real when the fitness superiority is only minimal. Will the more skilled survive the seemingly eternal inferiority during the competition? Under CA time becomes a central issue, with delusion becoming reality if the more skilled burns out during a long struggle. Thus, in the face of CA, the fittest survives only if it can persist, which prompts us to rename the principle “survival of the fittest and persistent” when considering CA competitions.

This observation may also shed light on the seemingly inherent difficulty of predicting success in real-world competitions by observing ongoing sample paths. Different empirical studies have alluded to this problem \[2, 29, 30\] as well as recent model driven studies \[31\]. Since direct competitions tend to be relatively very short and skill-differences tend to be
small it is well very possible that the winner when competition ended was not the fittest, adding to the difficulty of making accurate predictions.

Appendix A: Proofs

In this appendix, we provide proofs for our main results in Section IV. We will use the following additional notations and definitions.
• Denote the transition probability from state \((x_0, y_0)\) to state \((x, y)\) in \(t = x + y - x_0 - y_0\) steps by

\[
p_r(x_0, y_0; x, y) = \mathbb{P}_{CA,r}^{(x_0,y_0)}[(X_t, Y_t) = (x, y)].
\]

Note that the transition probability is nonzero only for this specific \(t\). Thus we will often omit to mention \(t\) explicitly hereafter and assume that the appropriate \(t\) has been chosen.

• Let \(\tau_n\) be the time of the \(n\)-th tie, which can be defined recursively by \(\tau_0 = -\infty\) and

\[
\tau_n = \inf\{t > \tau_{n-1} : X_t = Y_t\}, \quad n \geq 1.
\]

Note that \(T = \tau_N\).

• Denote by \(q_r(x_0, y_0)\) the probability of having no tie after leaving state \((x_0, y_0)\), i.e.,

\[
q_r(x_0, y_0) = \mathbb{P}_{CA,r}^{(x_0,y_0)}[X_t \neq Y_t, t \geq 1].
\]

Note that \(q_r(x_0, x_0) = \mathbb{P}_{CA,r}^{(x_0,x_0)}[\tau_2 = \infty]\) and \(q_r(x_0, y_0) = \mathbb{P}_{CA,r}^{(x_0,y_0)}[\tau_1 = \infty]\) for \(x_0 \neq y_0\).

• Denote by \(A_{n,t}(x, y)\) the set of paths that start from \((x, y)\) at time 0 and end with the \(n\)-th tie at time \(t\), i.e., \(\tau_n = t\).

1. Proof of Theorem \(\Box\)

Note that the CA\(_\pm\) model is the standard Pólya urn model. The proof of Theorem \(\Box\) combines known results for this model. Starting from the initial state \((x_0, y_0)\), \(X_t\) has a beta-binomial distribution with parameters \(x_0\) and \(y_0\) \([32]\). Note that the event \(X_t = Y_t\) occurs only if \(t = |x_0 - y_0| + 2k\) for some integer \(k \geq 0\). For such \(t\), \(X_t = Y_t\) if and only if \(X_t = z_0 + k\), where \(z_0 = \max\{x_0, y_0\}\). By Eq. (6.27) of \([32]\),

\[
\mathbb{P}_{CA,1}^{(x_0,y_0)}[X_t = Y_t] = \mathbb{P}_{CA,1}^{(x_0,y_0)}[X_t = z_0 + k] = \frac{B(z_0 + k, z_0 + k)}{B(x_0, y_0)} \binom{t}{k}.
\]

Recall that \(q_1(x, y)\) is the probability of having no tie after leaving state \((x, y)\). Thus

\[
\mathbb{P}_{CA,1}^{(x_0,y_0)}[T = t] = \mathbb{P}_{CA,1}^{(x_0,y_0)}[X_t = Y_t] \cdot q_1(z_0 + k, z_0 + k), \quad (A1)
\]

where the second factor on the right-hand side is the probability of having no tie after \(t\).
Recall that the exit probability \( E(x,y) \) in [25] is the probability of ever having a tie starting from \((x,y)\), including the initial state \((x,y)\). Thus for \( x \neq y \), \( q_1(x,y) \) is related to \( E(x,y) \) by

\[
q_1(x,y) = 1 - E(x,y).
\]

Using Eq. (22) of [25] for \( E(x,y) \), we obtain

\[
q_1(x+1,x) = q_1(x,x+1) = \frac{\Gamma(x+1/2)}{\Gamma(x+1)\Gamma(1/2)}.
\]

However, \( q_1(x,x) \neq E(x,x) = 1 \). By considering the one-step transition from \((x,x)\) to \((x+1,x)\) or \((x,x+1)\), we obtain

\[
q_1(x,x) = \frac{1}{2}q_1(x+1,x) + \frac{1}{2}q_1(x,x+1) = \frac{\Gamma(x+1/2)}{\Gamma(x+1)\Gamma(1/2)}.
\]

Eliminating \( \Gamma(x+1/2) \) by the identity

\[
\Gamma(2x) = \pi^{-1/2}2^{2x-1}\Gamma(x)\Gamma(x+1/2)
\]

in [23, Eq. (5.5.5)], and using \( \Gamma(x+1) = x\Gamma(x) \) and \( \Gamma(1/2) = \sqrt{\pi} \), we obtain

\[
q_1(x,x) = \frac{\Gamma(2x)}{x2^{2x-1}\Gamma(x)\Gamma(x+1/2)} = \frac{1}{x2^{2x-1}B(x,x)}.
\]  

Substitution of Eqs. (A1) and (A2) into Eq. (A1) yields

\[
\mathbb{P}_{\text{CA,1}}^{(x_0,y_0)}[T = t] = \frac{1}{B(x_0,y_0)} \cdot \frac{1}{(z_0 + k)2^{2k+2z_0-1}} \binom{t}{k}.
\]

For \( t = |x_0 - y_0| + 2k \), Stirling’s formula yields

\[
\binom{t}{k} \sim \sqrt{\frac{2}{\pi}} t^{-1/2} 2^k,
\]

and hence

\[
\mathbb{P}_{\text{CA,1}}^{(x_0,y_0)}[T = t] \sim \frac{1}{2^{x_0+y_0-5/2}\sqrt{\pi}B(x_0,y_0)} t^{-3/2}.
\]  

(A3)

It is well-known that as \( t \to \infty \), \( X_t/(X_t + Y_t) \) converges almost surely to a beta random variable \( V \). It follows that \( |X_t - Y_t|/(X_t + Y_t) \to |2V - 1| \). Thus, for \( V \neq 1/2 \), which holds almost surely, we have \( |X_t - Y_t|/(X_t + Y_t) > 0 \) for all large enough \( t \). Therefore, \( \mathbb{P}_{\text{CA,1}}^{(x_0,y_0)}[T = \infty] = 0 \). Summing over \( t \) in Eq. (A3), we obtain as \( t \to \infty \),

\[
\mathbb{P}_{\text{CA,1}}^{(x_0,y_0)}[T \geq t] \sim \frac{1}{2} \int_{t}^{\infty} \frac{1}{2^{x_0+y_0-5/2}\sqrt{\pi}B(x_0,y_0)} s^{-3/2}ds + \frac{1}{2} \int_{t}^{\infty} \frac{1}{2^{x_0+y_0-5/2}\sqrt{\pi}B(x_0,y_0)} t^{-1/2}ds,
\]

where we have used the fact that half of the terms are zero in the second step, and \( \int_{t}^{\infty} s^{-a}ds \approx \int_{t}^{\infty} s^{-a}ds \) in the third step. This completes the proof of Theorem II.
2. Proof of Theorem

Similar to Eq. (A1), we have

\[ \mathbb{P}^{(x_0, y_0)}_{CA, r} [T = t] = p_r(x_0, y_0; z_0, z_0 + k, z_0 + k) \cdot q_r(z_0 + k, z_0 + k). \quad (A4) \]

Thus the proof here amounts to finding expressions for both \( p_r(x_0, y_0; z_0 + k, z_0 + k) \) and \( q_r(z_0 + k, z_0 + k) \) in \( CA \neq T \). We break the proof into three lemmas.

Lemma 1.

\[ p_r(x_0, y_0; x_0 + k, y_0 + h) \geq \frac{(k + h)k}{(r-1)(rx_0 + y_0)} \left( \frac{x_0}{r_1} \right)^{r-1}, \quad (A5) \]

for all \( k \geq 0, h \geq 0 \).

Lemma 2.

\[ p_r(x_0, y_0; x_0 + k, y_0 + h) \leq \frac{(k + h)k}{(r-1)(rx_0 + y_0)} \left( \frac{x_0}{r_1} \right)^{r-1}, \quad (A6) \]

for all \( k \geq 0, h \geq 0 \).

Lemma 3. For \( r > 1 \),

\[ q_r(x, x) \rightarrow \frac{r - 1}{r + 1}, \quad (A7) \]

as \( x \to \infty \).

Before proving these lemmas, we first use them to prove Theorem.

Proof of Theorem. By Lemma 1, we have

\[ p_r(x_0, y_0; z_0 + k, z_0 + k) \geq \frac{(x_0 + z_0 - x_0)(y_0 + z_0 - y_0)}{(r_0 + y_0)^2k + 2z_0 - x_0 - y_0} \left( \frac{k + z_0 - x_0}{k + z_0 - y_0} \right)^2 \cdot \frac{\Gamma(k + z_0 - x_0 + 1)}{\Gamma(k + z_0 - y_0 + 1)} \cdot \frac{\Gamma(k + z_0 - x_0 - y_0 + 1)}{\Gamma(k + z_0 - x_0 + 1)} \]

Using the relation \( \Gamma(k + a)/\Gamma(k + b) \sim k^{a-b} \) as \( k \to \infty \), we obtain

\[ p_r(x_0, y_0; z_0 + k, z_0 + k) \geq \frac{(rx_0 + y_0)^{2k + 2z_0 - x_0 - y_0}}{2x_0 + y_0} \left( \frac{2k + 2z_0 - x_0 - y_0}{2r + 1} \right)^{2k + 2z_0 - x_0 - y_0} = 2(r + 1)x_0 \varphi_1(k)^{2k + 2z_0 - x_0 - y_0}, \]

where \( \varphi_1 \) is given by Eq. (4). Application of this asymptotic bound and Lemma 3 to Eq. (A4) yields

\[ \mathbb{P}^{(x_0, y_0)}_{CA, r} [T = t] \geq 2(r - 1)x_0 \varphi_1 t^{-(r-1)x_0 - 1}. \quad (A8) \]
Note that \( \mathbb{P}_{CA,r}^{(x_0,y_0)}[T = +\infty] = \mathbb{P}_{CA,r}^{(x_0,y_0)}[N = +\infty] = 0 \), where the second equality will follow from Theorem 1, so we will not provide a separate proof here. Summing over \( t \) in Eq. (A8) and noting that half of the terms are zero, we obtain as \( t \to \infty \),

\[
\mathbb{P}_{CA,r}^{(x_0,y_0)}[T \geq t] = \sum_{t'=t}^{\infty} \mathbb{P}_{CA,r}^{(x_0,y_0)}[T = t'] \gtrsim \int_{t}^{\infty} (r - 1)x_0\varphi_1s^{-(r-1)x_0-1}ds = \varphi_1t^{-(r-1)x_0},
\]

establishing the lower bound.

In a similar way, Lemma 2 yields

\[
p_r(x_0, y_0; z_0 + k, z_0 + k) \lesssim 2(r + 1)(x_0 - r^{-1})\varphi_2(2k)^{-(r-1)(x_0-r^{-1})-1},
\]

where \( \varphi_2 \) is given by Eq. (3). Application of this asymptotic bound and Lemma 4 to Eq. (A3) yields

\[
\mathbb{P}_{CA,r}^{(x_0,y_0)}[T = t] \lesssim 2(r - 1)(x_0 - r^{-1})\varphi_2t^{-(r-1)(x_0-r^{-1})-1},
\]

and

\[
\mathbb{P}_{CA,r}^{(x_0,y_0)}[T \geq t] = \sum_{t'=t}^{\infty} \mathbb{P}_{CA,r}^{(x_0,y_0)}[T = t'] \lesssim \varphi_2t^{-(r-1)(x_0-r^{-1})},
\]

establishing the upper bound.

Now we prove the lemmas. Recall that the transition probability \( p(x_0, y_0; x, y) \) of going from \( (x_0, y_0) \) to \( (x, y) \) satisfies the following recursion (Chapman-Kolmogorov equation),

\[
p_r(x_0, y_0; x, y) = \frac{r(x-1)}{r(x-1) + y} p_r(x_0, y_0; x - 1, y) + \frac{y - 1}{rx + y - 1} p_r(x_0, y_0; x, y - 1), \tag{A9}
\]

for \( x \geq x_0, y \geq y_0 \) and \( x + y \geq x_0 + y_0 + 1 \), with the boundary condition \( p_r(x_0, y_0; x, y) = 0 \) for \( x < x_0 \) or \( y < y_0 \). Note that we have replaced the one-step transition probabilities \( Q_{CA,r}(x - 1, y; x, y) \) and \( Q_{CA,r}(x, y - 1; x, y) \) by the expressions in Eq. (11).

**Proof of Lemma 1.** We will use the short-hand notation \( p(k, h) \) for \( p_r(x_0, y_0; x + k, y_0 + h) \), and \( \psi(k, h) \) for the right-hand side of Eq. (A3). We first prove the boundary case for \( k = 0 \). By Eq. (A3), for \( h \geq 1 \),

\[
p(0, h) = \frac{y_0 + h - 1}{rx_0 + y_0 + h - 1} p(0, h - 1),
\]

which is a simple recursion in \( h \) and can be expanded to yield

\[
p(0, h) = \frac{(y_0)_h}{(rx_0 + y_0)_h} p(0, 0) = \frac{(y_0)_h}{(rx_0 + y_0)_h} = \psi(0, h),
\]

25
which yields Eq. (A5) for $k = 0$ and $h \geq 1$. Here we have used $p(0, 0) = p_r(x_0, y_0; x_0, y_0) = 1$.

Similarly, for the other boundary case $h = 0, k \geq 1$, we have

$$p(k, 0) = \frac{(x_0)_k}{(x_0 + r^{-1}y_0)_k} p(0, 0) = \frac{(x_0)_k}{(x_0 + r^{-1}y_0)_k} \geq \frac{(x_0)_k}{(rx_0 + y_0)_k} = \psi(k, 0),$$

where the last inequality is because $(x)_k$ increases with $x$, and $x_0 + r^{-1}y_0 \leq rx_0 + y_0$.

For the general case, we use induction on $k + h$. The base case $k + h = 1$ is already proven, since either $k = 0$ or $h = 0$ when $k + h = 1$. Assume Eq. (A5) holds for $k + h = m \geq 1$. Consider $k + h = m + 1$. We can also assume $k \geq 1$ and $h \geq 1$, since we have proven the boundary cases for $k = 0$ or $h = 0$. The recursion in Eq. (A5) yields

$$p(k, h) = \frac{r(x_0 + k - 1)}{rk + h + c_0 - r} p(k - 1, h) + \frac{y_0 + h - 1}{rk + h + c_0 - 1} p(k, h - 1)$$

$$\geq \frac{r(x_0 + k - 1)}{rk + h + c_0 - 1} p(k - 1, h) + \frac{y_0 + h - 1}{rk + h + c_0 - 1} p(k, h - 1),$$

where $c_0 = rx_0 + y_0$.

Applying the induction hypothesis $p(k - 1, h) \geq \psi(k - 1, h)$ and $p(k, h - 1) \geq \psi(k, h - 1)$ to the above inequality yields

$$p(k, h) \geq \frac{r(x_0 + k - 1)}{rk + h + c_0 - 1} \psi(k - 1, h) + \frac{y_0 + h - 1}{rk + h + c_0 - 1} \psi(k, h - 1)$$

$$= \frac{(rk + h)(k + h + c_0 - 1)}{(k + h)(rk + h + c_0 - 1)} \psi(k, h),$$

where in the last step we have used

$$\psi(k - 1, h) = \frac{k}{k + h} \cdot \frac{k + h + c_0 - 1}{x_0 + k - 1} \psi(k, h),$$

and

$$\psi(k, h - 1) = \frac{h}{k + h} \cdot \frac{k + h + c_0 - 1}{y_0 + h - 1} \psi(k, h).$$

To complete the proof, it suffices to show that

$$\frac{(rk + h)(k + h + c_0 - 1)}{(k + h)(rk + h + c_0 - 1)} \geq 1,$$

but this is equivalent to $r \geq 1$, which is true by assumption.

Proof of Lemma 4. The proof of Lemma 4 follows the same line of reasoning as that used to prove Lemma 3. The boundary cases can be verified directly. We only outline the induction step here. Applying Eq. (A6) to the right-hand side of Eq. (A6) yields

$$p(k, h) \leq \frac{r(x_0 + k - 1)}{rk + h + c_0 - r (r^{-1}) k - 1 (c_0)_h} \frac{(x_0)_k(y_0)_h}{(rk + h + c_0 - 1 (r^{-1}) k (c_0)_h - 1)}$$

$$\frac{y_0 + h - 1}{rk + h + c_0 - 1 (r^{-1}) k (c_0)_h - 1} \psi(k, h).$$

26
For fixed $k$ where we have used Eq. (3.3) in \[ \] and end with the $n$-th tie at time $2k$, i.e., $\tau_n = 2k$. Let $A_{n, 2k} = A_{n, 2k}(0, 0)$. Note that the paths in $A_{n, 2k}(x, x)$ are exactly the paths in $A_{n, 2k}$ translated by $(x, x)$. Let $\tilde{\pi} \in A_{n, 2k}$ and its state at time $t$ be $\tilde{\pi}_t = (\tilde{x}_t, \tilde{y}_t)$. The translation of $\tilde{\pi}$ by $(x, x)$, denoted $x + \tilde{\pi}$, is a path in $A_{n, 2k}(x, x)$, whose probability in the CA model is given by

$$P_{CA, r}^{(x, x)}[x + \tilde{\pi}] = \prod_{j=0}^{2k-1} \left( \frac{r(x + \tilde{x}_j)}{r(x + \tilde{x}_j) + (x + \tilde{y}_j)} \right)^{\tilde{x}_{j+1} - \tilde{x}_j} \cdot \prod_{j=0}^{2k-1} \left( \frac{r(x + \tilde{y}_j)}{r(x + \tilde{x}_j) + (x + \tilde{y}_j)} \right)^{\tilde{y}_{j+1} - \tilde{y}_j}.$$

For fixed $k$ and $\tilde{\pi}$, as $x \to \infty$, $P_{CA, r}^{(x, x)}[x + \tilde{\pi}]$ converges to

$$\prod_{j=0}^{2k-1} \left( \frac{r}{r+1} \right)^{\tilde{x}_{j+1} - \tilde{x}_j} \left( \frac{1}{r+1} \right)^{\tilde{y}_{j+1} - \tilde{y}_j} = P_{RW, r}^{(0, 0)}[\tilde{\pi}],$$

which corresponds to the probability of the path $\tilde{\pi}$ in a random walk with parameter $r/(r+1)$. Thus, as $x \to \infty$,

$$P_{CA, r}^{(x, x)}[\tau_n = 2k] = \sum_{\tilde{\pi} \in A_{n, 2k}} P_{CA, r}^{(x, x)}[x + \tilde{\pi}] \to \sum_{\tilde{\pi} \in A_{n, 2k}} P_{RW, r}^{(0, 0)}[\tilde{\pi}] = P_{RW, r}^{(0, 0)}[\tau_n = 2k].$$

After summing over $k$ and using the Dominated Convergence Theorem, we obtain

$$P_{CA, r}^{(x, x)}[\tau_n < \infty] = \sum_{k=1}^{\infty} P_{CA, r}^{(x, x)}[\tau_n = 2k] \to \sum_{k=1}^{\infty} P_{RW, r}^{(0, 0)}[\tau_n = 2k] = P_{RW, r}^{(0, 0)}[\tau_n < \infty].$$

In particular,

$$q_r(x, x) = 1 - P_{CA, r}^{(x, x)}[\tau_2 < \infty] \to 1 - P_{RW, r}^{(0, 0)}[\tau_2 < \infty] = \frac{r - 1}{r + 1},$$

where we have used Eq. (3.3) in [28] for $P_{RW, r}^{(0, 0)}[\tau_2 < \infty]$ in the last step. \qed
3. Proof of Theorem

Recall that $A_{n,t}(x_0, y_0)$ is the set of paths starting from $(x_0, y_0)$ that end with the $n$-th tie at time $t$, i.e., $\tau_n = t$. We will use the short-hand notation $A_{n,t}$ for $A_{n,t}(x_0, y_0)$. As in Section A, the set $A_{n,t}$ is non-empty only if $t = |x_0 - y_0| + 2k$ for some integer $k \geq n - 1$, in which case, every path in $A_{n,t}$ ends in state $(z_0 + k, z_0 + k)$ with $z_0 = \max\{x_0, y_0\}$. Recall from [25] that the probability of any path $\pi$ connecting states $(x_0, y_0)$ and $(x, y)$ is

$$P_{CA,1}(x, y) = \frac{B(x, y)}{B(x_0, y_0)} = \frac{B(x, y)}{B(x_0, y_0)} 2^{t} P_{RW,1}(x_0, y_0)[\pi].$$

Summing over $\pi \in A_{n,t}$, where $x = y = z_0 + k$, we obtain

$$P_{CA,1}(x_0, y_0)[\tau_n = t] = \frac{B(z_0 + k, z_0 + k)}{B(x_0, y_0)} 2^{t} P_{RW,1}(x_0, y_0)[\tau_n = t]. \quad (A10)$$

Thus the probability of having the $n$-th and also the last tie at time $t$ is given by

$$P_{CA,1}(x_0, y_0)[T = t, N = n] = P_{CA,1}(x_0, y_0)[\tau_n = t] \cdot q_1(z_0 + k, z_0 + k) = \frac{1}{2^{x_0 + y_0 - 2} B(x_0, y_0)} \cdot \frac{1}{t + x_0 + y_0} P_{RW,1}(x_0, y_0)[\tau_n = t] \quad (A11)$$

where we have used Eqs. (A10) and (A11) in the last step. Note that $P_{RW,1}(x_0, y_0)[\tau_n = t]$ is the probability $f_{n,t}(d_0)$ of the $n$-th visit to the origin at time $t$ in a simple symmetric random walk starting from $d_0 = |x_0 - y_0|$. Summing over $t$ in (A11), we obtain

$$P_{CA,1}(x_0, y_0)[N = n] = \frac{1}{2^{x_0 + y_0 - 2} B(x_0, y_0)} \sum_{k=n-1}^{\infty} \frac{f_{n,d_0+2k}(d_0)}{2k + d_0 + x_0 + y_0} = \frac{G_n(1; d_0)}{2^{x_0 + y_0 - 2} B(x_0, y_0)}, \quad (A12)$$

where

$$G_n(z; d_0) = \sum_{k=n-1}^{\infty} \frac{f_{n,d_0+2k}(d_0)}{2k + d_0 + x_0 + y_0} z^{d_0+2k}.$$

To simplify $G_n(z; d_0)$, we have

$$\frac{d}{dz}[z^{x_0 + y_0} G_n(z; d_0)] = z^{x_0 + y_0 - 1} \sum_{k=n-1}^{\infty} f_{n,d_0+2k}(d_0) z^{d_0+2k} = z^{x_0 + y_0 - 1} \Phi_n(z; d_0), \quad (A13)$$

where $\Phi_n(z; d_0) = \sum_{k=n-1}^{\infty} f_{n,d_0+2k}(d_0) z^{d_0+2k}$ is the generating function of the probability distribution of the $n$-th visit to the origin in a simple random walk starting from $d_0$. Let $F_1(z)$ be the generating function of the distribution of the time of the first return to the
origin in a simple random walk starting from the origin. The standard renewal argument (see e.g. XI.3.d of [34]) shows that \( \Phi_n(z; d_0) \) is given by

\[
\Phi_n(z; d_0) = \Phi_1(z; 1)^d_0 F_1(z)^{n-1},
\]

where \( \Phi_1(z; 1) \) and \( F_1(z) \) are given by Eqs. (3.6) and (3.14) of [34, Chap. XI], respectively. Therefore,

\[
\Phi_n(z; d_0) = z^{-d_0} \left( 1 - \sqrt{1 - z^2} \right)^{n+d_0-1}.
\]  \hspace{1cm} (A14)

Substituting Eq. (A14) into Eq. (A13) and integrating from 0 to 1 yields

\[
G_n(1; d_0) = \int_0^1 z^{2 \min\{x_0, y_0\} - 1} \left( 1 - \sqrt{1 - z^2} \right)^{n+d_0-1} dz,
\]

where we have used \( x_0 + y_0 - d_0 = 2 \min\{x_0, y_0\} \). A change of variable \( u = \sqrt{1 - z^2} \) yields

\[
G_n(1; d_0) = \int_0^1 u(1 - u^2)^{\min\{x_0, y_0\} - 1} (1 - u)^{n+d_0-1} du,
\]

which is upper bounded by

\[
G_n(1; d_0) \leq \int_0^1 u(1 - u)^{n+d_0-1} du = B(2, n + d_0),
\]  \hspace{1cm} (A15)

and lower bounded by

\[
G_n(1; d_0) \geq \int_0^1 u(1 - u)^{\min\{x_0, y_0\} - 1} (1 - u)^{n+d_0-1} du = B(2, n + \max\{x_0, y_0\} - 1),
\]  \hspace{1cm} (A16)

where we have used \( \min\{x_0, y_0\} + d_0 = \max\{x_0, y_0\} \). Applying Eqs. (A15) and (A16) to Eq. (A12) yields

\[
\frac{B(2, n + \max\{x_0, y_0\} - 1)}{2^{x_0 + y_0 - 2} B(x_0, y_0)} \leq \mathbb{P}_{CA, 1}^{(x_0, y_0)} [N = n] \leq \frac{B(2, n + d_0)}{2^{x_0 + y_0 - 2} B(x_0, y_0)},
\]

Note that \( \mathbb{P}_{CA, 1}^{(x_0, y_0)} [N = \infty] = \mathbb{P}_{CA, 1}^{(x_0, y_0)} [T = \infty] = 0 \). Summing over \( n \) and using \( \sum_{m=n}^{\infty} B(2, m) = n^{-1} \), we obtain

\[
\frac{1}{2^{x_0 + y_0 - 2} B(x_0, y_0)} \cdot \frac{1}{n + \max\{x_0, y_0\} - 1} \leq \mathbb{P}_{CA, 1}^{(x_0, y_0)} [N \geq n] \leq \frac{1}{2^{x_0 + y_0 - 2} B(x_0, y_0)} \cdot \frac{1}{n + d_0},
\]

which immediately yields Eq. (3).
4. Proof of Theorem

We first prove the following lemma.

**Lemma 4.** The probability \( \mathbb{P}_{CA,r}^{(x_0,y_0)} [\tau_1 < \infty] \) of ever having a tie is bounded as follows,

\[
\mathbb{P}_{CA,r}^{(x_0,y_0)} [\tau_1 < \infty] \leq \begin{cases} 
1, & x_0 \leq y_0, \\
\frac{(y_0)x_0-y_0}{(r x_0 + y_0)x_0-y_0} (1 + \frac{1}{r})^{x_0-y_0}, & x_0 > y_0.
\end{cases}
\]

Note that \( \mathbb{P}_{CA,r}^{(x_0,y_0)} [\tau_1 < \infty] \) is the exit probability \( E(x,y) \) in [25] when \( r = 1 \).

**Proof.** The case \( x_0 = y_0 \) is trivial since \( \tau_1 = 0 \). When \( x_0 < y_0 \), Theorem 3.21 of [35] yields \( Y_t/X_t \to 0 \) almost surely, from which it follows that \( X_t > Y_t \) eventually and hence \( \mathbb{P}_{CA,r}^{(x_0,y_0)} [\tau_1 < \infty] = 1 \).

Now assume \( x_0 > y_0 \). Recall that \( A_{1,t}(x_0,y_0) \) is the set of paths starting from \((x_0,y_0)\) that end with the first tie at time \( t \). Note that \( A_{1,t}(x_0,y_0) \) is nonempty only if \( t = d_0 + 2k \), where \( d_0 = x_0 - y_0 \) and \( k \geq 0 \). Let \( \pi \in A_{1,t}(x_0,y_0) \) and its state at time \( j \) be \( \pi_j = (x_j,y_j) \).

The probability of the path \( \pi \) is given by

\[
\mathbb{P}_{CA,r}^{(x_0,y_0)} [\pi] = \prod_{j=0}^{t-1} \left( \frac{r x_j}{r x_j + y_j} \right)^{x_{j+1}-x_j} \left( \frac{y_j}{r x_j + y_j} \right)^{y_{j+1}-y_j} = \frac{r^{x_t-x_0}(x_0)x_t-x_0(y_0)y_t-y_0}{\prod_{j=0}^{t-1}(r x_j + y_j)},
\]

where in the last step we have used \( x_j + y_j = x_0 + y_0 + j \). Note that \( \mathbb{P}_{CA,r}^{(x_0,y_0)} [\pi] \) is maximized if the \( x_j \)'s are minimized, subject to the constraints that the \( x_j \)'s increase monotonically from \( x_0 \) to \( x_t \) with step size 0 or 1, and that \( x_j > y_j \) for all \( 1 \leq j \leq t-1 \), or equivalently \( x_j > x_0 + (j - d_0)/2 \). This is achieved by the following sequence,

\[
\begin{align*}
x_j^* &= \begin{cases} 
    x_0, & j = 0,1,\ldots,d_0-1; \\
    x_0 + \lfloor (j-d_0)/2 \rfloor + 1, & j = d_0,d_0+1,\ldots,t-1; \\
    x_t, & j = t.
\end{cases}
\end{align*}
\]

The corresponding path \( \pi^* \) has probability

\[
\mathbb{P}_{CA,r}^{(x_0,y_0)} [\pi^*] = \prod_{j=0}^{d_0-2} \frac{y_0 + j}{r x_j + y_0 + j} \prod_{x=x_0}^{x_{t-1}} \frac{r x}{r x + (x-1)} \cdot \frac{x-1}{r(x+1) + (x-1)} \frac{x_t-1}{r x_t + (x_t-1)},
\]

30
which, after arrangement, yields,

\[
P(x_0, y_0) \geq \prod_{j=0}^{d_0-1} \frac{y_0 + j}{r x_0 + y_0 + j} \prod_{x=x_0}^{x-1} \frac{r x}{(r + 1)x + r} \cdot \frac{x}{(r + 1)x + (r - 1)}
\]

Thus we have

\[
P(x_0, y_0) \geq \prod_{x=x_0}^{x} \frac{r x}{(r + 1)x + r}
\]

and, after summing over \( \pi \in A_{1,t}(x_0, y_0) \),

\[
P(x_0, y_0) \leq \prod_{x=x_0}^{x} \frac{r x}{(r + 1)x + r}
\]

Summing over \( t \), we obtain

\[
P(x_0, y_0) \leq \prod_{x=x_0}^{x} \frac{r x}{(r + 1)x + r}
\]

By Eq. (3.9) and XI.3.d of [34], \( P^{(x_0, y_0)}_{R\tilde{W}, r} [\tau_1 < \infty] = r^{-d_0} \), from which the desired conclusion follows.

**Corollary 1.** The probability of having at least one more tie starting from a tie state \((x, x)\) is bounded by

\[
P(x, x) < \infty \leq \frac{r}{r + 1}.
\]

**Proof.** By considering the one-step transition from \((x, x)\) into \((x, x + 1)\) or \((x + 1, x)\), we obtain

\[
P(x, x) < \infty = \frac{r}{r + 1} P^{(x+1, x)}_{CA, r} [\tau_1 < \infty] + \frac{1}{r + 1} P^{(x+1, x)}_{CA, r} [\tau_1 < \infty]
\]

where the first inequality follows from Lemma [4].

Now we prove Theorem [4].
Proof of Theorem 4. Let \( Z_n \) be the common value of \( X_t \) and \( Y_t \) at \( t = \tau_n \), i.e., \( Z_n = X_{\tau_n} \). Conditioned on \( \tau_n < \infty \) and \( Z_n = z \), the probability of \( \tau_{n+1} < \infty \) is just the probability of having a tie after leaving \((z, z)\). Thus

\[
P^{(x_0, y_0)}_{CA, r} [\tau_{n+1} < \infty \mid \tau_n < \infty, Z_n = z] = P^{(z,z)}_{CA, r} [\tau_2 < \infty] \leq \frac{2}{r + 1},
\]

by Corollary 1. Removal of the conditioning yields

\[
P^{(x_0, y_0)}_{CA, r} [\tau_{n+1} < \infty \mid \tau_n < \infty] \leq \frac{2}{r + 1}.
\]

It follows that

\[
P^{(x_0, y_0)}_{CA, r} [N \geq n] = P^{(x_0, y_0)}_{CA, r} [\tau_n < \infty] = P^{(x_0, y_0)}_{CA, r} [\tau_1 < \infty] \prod_{i=1}^{n-1} P^{(x_0, y_0)}_{CA, r} [\tau_{i+1} < \infty \mid \tau_i < \infty]
\]

\[
\leq P^{(x_0, y_0)}_{CA, r} [\tau_1 < \infty] \left( \frac{2}{r + 1} \right)^{n-1}.
\]

An application of Lemma 3 completes the proof. \( \square \)
